

Chapter 1

Characterizing Deep Gaussian Process Models

“On a given day, would I rather be wrestling with a sampler, or proving theorems?”

Peter Orbanz, personal communication

Choosing appropriate architectures and regularization strategies of deep networks is crucial to good predictive performance. To shed light on this problem, we analyze the analogous problem of constructing useful priors on compositions of functions. Specifically, we study the deep Gaussian process, a type of infinitely-wide, deep neural network. We show that in standard architectures, the representational capacity of the network tends to capture fewer degrees of freedom as the number of layers increases, retaining only a single degree of freedom in the limit. We propose an alternate network architecture which does not suffer from this pathology. We also examine deep covariance functions, obtained by composing infinitely many feature transforms. Lastly, we characterize the class of models obtained by performing dropout on Gaussian processes.

1.1 Introduction

Much recent work on deep networks has focused on weight initialization (?), regularization (?) and network architecture (?). However, the interactions between these different design decisions can be complex and difficult to characterize. We propose to approach the design of deep architectures by examining the problem of assigning priors to nested compositions of functions. Well-defined priors allow us to explicitly examine

the assumptions being made about functions we may wish to learn. If we can identify classes of priors that give our models desirable properties, these in turn may suggest regularization, initialization, and architecture choices that also provide such properties.

Fundamentally, a multilayer neural network implements a composition of vector-valued functions, one per layer. Hence, understanding properties of such function compositions helps us gain insight into deep networks. In this paper, we examine a simple and flexible class of priors on compositions of functions, namely deep Gaussian processes (?). Deep GPs are simply priors on compositions of vector-valued functions, where each output of each layer is drawn independently from a GP prior:

$$\mathbf{f}^{(1:L)}(\mathbf{x}) = \mathbf{f}^{(L)}(\mathbf{f}^{(L-1)}(\dots \mathbf{f}^{(2)}(\mathbf{f}^{(1)}(\mathbf{x})) \dots)) \quad (1.1)$$

$$\mathbf{f}_d^{(\ell)} \stackrel{\text{ind}}{\sim} \text{GP}(0, k_d^\ell(\mathbf{x}, \mathbf{x}')) \quad (1.2)$$

These models correspond to a certain type of infinitely-wide multi-layer perceptron (MLP), and as such make canonical candidates for generative models of functions that closely relate to neural networks.

By characterizing these models, this paper shows that representations based on repeated composition of independently-initialized functions exhibit a pathology where the representation becomes invariant to all but one direction of variation. This corresponds to an eventual debilitating decrease in the information capacity of networks as a function of their number of layers. However, we will demonstrate that a simple change in architecture — namely, connecting the input to each layer — fixes this problem.

We also present two related analyses: first, we examine the properties of an arbitrarily deep fixed feature transforms (“deep kernels”). Second, we characterise the prior obtained by performing dropout on GPs, showing equivalences to existing models.

1.2 Relating Deep Neural Nets and Deep Gaussian Processes

1.2.1 Single-layer Models

In the typical definition of an MLP, the hidden units of the first layer are defined as:

$$\mathbf{h}^{(1)}(\mathbf{x}) = \sigma(\mathbf{b}^{(1)} + \mathbf{W}^{(1)}\mathbf{x}) \quad (1.3)$$

Fig. 1.1 a): GPs can be understood as a one-hidden-layer MLP with infinitely many hidden units. There are two interpretations of deep GPs as neural networks: b): As a neural network with a finite number of hidden units, each with a different non-parametric activation function. c) Alternatively, we can consider every second layer to be a random linear combination of an infinite number of fixed, parametric hidden units.

where \mathbf{h} are the hidden unit activations, \mathbf{b} is a bias vector, \mathbf{W} is a weight matrix and σ is a one-dimensional nonlinear function applied element-wise. The output vector $f(\mathbf{x})$ is simply a weighted sum of these hidden unit activations:

$$f(\mathbf{x}) = \mathbf{V}^{(1)} \sigma(\mathbf{b}^{(1)} + \mathbf{W}^{(1)} \mathbf{x}) = \mathbf{V}^{(1)} \mathbf{h}^{(1)}(\mathbf{x}) \quad (1.4)$$

where $\mathbf{V}^{(1)}$ is another weight matrix.

There exists a correspondence between one-layer MLPs and GPs (?). GPs can be viewed as a prior on neural networks with infinitely many hidden units, and unknown weights. More precisely, for any model of the form

$$f(\mathbf{x}) = \frac{1}{K} \alpha^\top \mathbf{h}(\mathbf{x}) = \frac{1}{K} \sum_{i=1}^K \alpha_i h_i(\mathbf{x}), \quad (1.5)$$

with fixed features $[h_1(\mathbf{x}), \dots, h_K(\mathbf{x})]^\top = \mathbf{h}(\mathbf{x})$ and i.i.d. α 's with zero mean and finite variance σ^2 , the central limit theorem implies that as the number of features

K grows, any two function values $f(\mathbf{x}), f(\mathbf{x}')$ have a joint distribution approaching $\mathcal{N}\left(0, \frac{\sigma^2}{K} \sum_{i=1}^K h_i(\mathbf{x})h_i(\mathbf{x}')\right)$. A joint Gaussian distribution between any set of function values is the definition of a Gaussian process.

The result is surprisingly general: it puts no constraints on the features (other than having uniformly bounded activation), nor does it require that the feature weights α be Gaussian distributed.

We can also work backwards to derive a one-layer MLP from any GP. Mercer’s theorem implies that any positive-definite kernel function corresponds to an inner product of features: $k(\mathbf{x}, \mathbf{x}') = \mathbf{h}(\mathbf{x})^\top \mathbf{h}(\mathbf{x}')$. Thus in the one-hidden-layer case, the correspondence between MLPs and GPs is simple: the features $\mathbf{h}(\mathbf{x})$ of the kernel correspond to the hidden units of the MLP.

1.2.2 Multiple Hidden Layers

In an MLP, the ℓ th layer units are given by the recurrence

$$\mathbf{h}^{(\ell)}(\mathbf{x}) = \sigma\left(\mathbf{b}^{(\ell)} + \mathbf{W}^{(\ell)}\mathbf{h}^{(\ell-1)}(\mathbf{x})\right) . \quad (1.6)$$

This architecture is shown in figure 1.1b. For example, if we extend the model given by (1.4) to have two layers of feature mappings, the resulting model is

$$f(\mathbf{x}) = \frac{1}{K} \alpha^\top \mathbf{h}^{(2)}\left(\mathbf{h}^{(1)}(\mathbf{x})\right) . \quad (1.7)$$

If the features $\mathbf{h}(\mathbf{x})$ are considered fixed with only the last layer weights α unknown, this model corresponds to a GP with a “deep kernel”:

$$k(\mathbf{x}, \mathbf{x}') = \left(\mathbf{h}^{(2)}(\mathbf{h}^{(1)}(\mathbf{x}))\right)^\top \mathbf{h}^{(2)}(\mathbf{h}^{(1)}(\mathbf{x}')) \quad (1.8)$$

These models, examined in section 1.6, imply a fixed representation as opposed to a prior over representations, which is what we wish to analyze in this paper.

To construct a neural network with fixed nonlinearities corresponding to a deep GP, one must introduce a second layer in between each infinitely-wide set of fixed basis functions, as in figure 1.1c. The D_ℓ outputs $\mathbf{f}^{(\ell)}(\mathbf{x})$ in between each layer are weighted sums (with unknown weights) of the fixed hidden units of the layer below, and the next layer’s hidden units depend only on these D_ℓ outputs.

This alternating-layer architecture has an interpretation as a series of linear infor-

Fig. 1.2 One-dimensional draws from a deep gp prior. After a few layers, the functions begin to be either nearly flat, or highly varying, everywhere. This is a consequence of the distribution on derivatives becoming heavy-tailed.

mation bottlenecks. We can simply substitute (1.4) into (1.6) to get

$$\mathbf{h}^{(\ell)}(\mathbf{x}) = \sigma \left(\mathbf{b}^{(\ell)} + \mathbf{W}^{(\ell)} \mathbf{V}^{(\ell-1)} \mathbf{h}^{(\ell-1)}(\mathbf{x}) \right). \quad (1.9)$$

Thus, ignoring the intermediate outputs $\mathbf{f}^{(\ell)}(\mathbf{x})$, a deep GP is an infinitely-wide, deep MLP with each pair of layers connected by random, rank- D_ℓ matrices $\mathbf{W}^{(\ell)} \mathbf{V}^{(\ell-1)}$.

A more direct way to construct a network architecture corresponding to a deep GP is to integrate out all $\mathbf{V}^{(\ell)}$, and view deep GPs as a neural network with a finite number of nonparametric, GP-distributed basis functions at each layer, in which $\mathbf{f}^{(1:\ell)}(\mathbf{x})$ represent the output of the hidden nodes at the ℓ^{th} layer. This second view lets us compare deep GP models to standard neural net architectures more directly.

1.3 Characterizing Deep Gaussian Processes

In this section, we develop several theoretical results that explore the behavior of deep GPs as a function of their depth. This will allow us in section 1.4 to formally identify a pathology that emerges in very deep networks.

Specifically, we will show that the size of the derivative of a one-dimensional deep GP becomes log-normal distributed as the network becomes deeper. We'll also show that the Jacobian of a multivariate deep GP is a product of independent Gaussian matrices with independent entries.

1.3.1 One-dimensional Asymptotics

In this section, we derive the limiting distribution of the derivative of an arbitrarily deep, one-dimensional GP with a squared-exp kernel:

$$k_{\text{SE}}(x, x') = \sigma^2 \exp\left(\frac{-(x - x')^2}{2w^2}\right). \quad (1.10)$$

The hyperparameter σ^2 controls the variance of functions drawn from the prior, and the hyperparameter w controls the smoothness. The derivative of a GP with a squared-exp kernel is pointwise distributed as $\mathcal{N}(0, \sigma^2/w^2)$. Intuitively, a GP is likely to have large derivatives if it has high variance and small lengthscales.

By the chain rule, the derivative of a one-dimensional deep GP is simply a product of its (independent) derivatives. The distribution of the absolute value of this derivative is a product of half-normals, each with mean $\sqrt{2\sigma^2/\pi w^2}$.

If we choose kernel parameters so that $\sigma^2/w^2 = \pi/2$, then the expected magnitude of the derivative remains constant regardless of the depth.

The log of the magnitude of the derivatives has moments

$$\begin{aligned} m_{\log} &= \mathbb{E} \left[\log \left| \frac{\partial f(x)}{\partial x} \right| \right] = 2 \log \left(\frac{\sigma}{w} \right) - \log 2 - \gamma \\ v_{\log} &= \mathbb{V} \left[\log \left| \frac{\partial f(x)}{\partial x} \right| \right] = \frac{\pi^2}{4} + \frac{\log^2 2}{2} - \gamma^2 - \gamma \log 4 + 2 \log \left(\frac{\sigma}{w} \right) \left[\gamma + \log 2 - \log \left(\frac{\sigma}{w} \right) \right] \end{aligned} \quad (1.11)$$

where $\gamma \approx 0.5772$ is Euler's constant. Since the second moment is finite, by the central limit theorem, the limiting distribution of the size of the gradient approaches log-normal as L grows:

$$\begin{aligned} \log \left| \frac{\partial f^{(1:L)}(x)}{\partial x} \right| &= \sum_{\ell=1}^L \log \left| \frac{\partial f^{(\ell)}(x)}{\partial x} \right| \\ \implies \log \left| \frac{\partial f^{(1:L)}(x)}{\partial x} \right| &\stackrel{L \rightarrow \infty}{\rightsquigarrow} \mathcal{N}(Lm_{\log}, L^2v_{\log}) \end{aligned} \quad (1.12)$$

Even if the expected magnitude of the derivative remains constant, the variance of the log-normal distribution grows without bound as the depth increases. Because the log-normal distribution is heavy-tailed and its domain is bounded below by zero, the derivative will become very small almost everywhere, with rare but very large jumps.

Figure 1.2 shows this behavior in a draw from a 1D deep GP prior, at varying depths. This figure also shows that once the derivative in one region of the input space becomes very large or very small, it is likely to remain that way in subsequent layers.

1.3.2 Distribution of the Jacobian

We now derive the distribution on Jacobians of multivariate functions drawn from a deep GP prior.

Lemma 1.3.1. *The partial derivatives of a function mapping $\mathbb{R}^D \rightarrow \mathbb{R}$ drawn from a GP prior with a product kernel are independently Gaussian distributed.*

Proof. Because differentiation is a linear operator, the derivatives of a function drawn from a GP prior are also jointly Gaussian distributed. The covariance between partial derivatives w.r.t. input dimensions d_1 and d_2 of vector \mathbf{x} are given by ?:

$$\text{cov} \left(\frac{\partial f(\mathbf{x})}{\partial x_{d_1}}, \frac{\partial f(\mathbf{x})}{\partial x_{d_2}} \right) = \frac{\partial^2 k(\mathbf{x}, \mathbf{x}')}{\partial x_{d_1} \partial x'_{d_2}} \Big|_{\mathbf{x}=\mathbf{x}'} \quad (1.13)$$

If our kernel is a product over individual dimensions $k(\mathbf{x}, \mathbf{x}') = \prod_d k_d(x_d, x'_d)$, as in the case of the squared-exp kernel, then the off-diagonal entries are zero, implying that all elements are independent. \square

In the case of the multivariate squared-exp kernel, the covariance between derivatives has the form:

$$\begin{aligned} f(\mathbf{x}) &\sim \text{GP} \left(0, \sigma^2 \prod_{d=1}^D \exp \left(-\frac{1}{2} \frac{(x_d - x'_d)^2}{w_d^2} \right) \right) \\ \implies \text{cov} \left(\frac{\partial f(\mathbf{x})}{\partial x_{d_1}}, \frac{\partial f(\mathbf{x})}{\partial x_{d_2}} \right) &= \begin{cases} \frac{\sigma^2}{w_{d_1}^2} & \text{if } d_1 = d_2 \\ 0 & \text{if } d_1 \neq d_2 \end{cases} \end{aligned} \quad (1.14)$$

Lemma 1.3.2. *The Jacobian of a set of D functions $\mathbb{R}^D \rightarrow \mathbb{R}$ drawn independently from a GP prior with a product kernel is a $D \times D$ matrix of independent Gaussian R.V.'s*

Proof. The Jacobian of the vector-valued function $\mathbf{f}(\mathbf{x})$ is a matrix J with elements $J_{ij} = \frac{\partial f_i(\mathbf{x})}{\partial x_j}$. Because we've assumed that the GPs on each output dimension $\mathbf{f}_d(\mathbf{x})$ are independent (1.2), it follows that each row of J is independent. Lemma 1.3.1 shows that the elements of each row are independent Gaussian. Thus all entries in the Jacobian of a GP-distributed transform are independent Gaussian R.V.'s. \square

Theorem 1.3.3. *The Jacobian of a deep GP with a product kernel is a product of independent Gaussian matrices, with each entry in each matrix being drawn independently.*

Fig. 1.3 Representing a 1-D manifold. Colors show the output of the computed representation as a function of the input space. The representation (blue & green) is invariant in directions orthogonal to the data manifold (white), making it robust to noise in those directions, and reducing the number of parameters needed to represent a datapoint. The representation also changes in directions tangent to the manifold, preserving information for later layers.

Proof. When composing L different functions, we'll denote the *immediate* Jacobian of the function mapping from layer $\ell - 1$ to layer ℓ as $J^\ell(\mathbf{x})$, and the Jacobian of the entire composition of L functions by $J^{1:L}(\mathbf{x})$. By the multivariate chain rule, the Jacobian of a composition of functions is simply the product of the immediate Jacobian matrices of each function. Thus the Jacobian of the composed (deep) function $\mathbf{f}^{(L)}(\mathbf{f}^{(L-1)}(\dots \mathbf{f}^{(3)}(\mathbf{f}^{(2)}(\mathbf{f}^{(1)}(\mathbf{x}))) \dots)$ is

$$J^{1:L}(\mathbf{x}) = J^L J^{(L-1)} \dots J^3 J^2 J^1. \quad (1.15)$$

By lemma 1.3.2, each $J_{i,j}^\ell \stackrel{\text{ind}}{\sim} \mathcal{N}$, so the complete Jacobian is a product of independent Gaussian matrices, with each entry of each matrix drawn independently. \square

Theorem 1.3.3 allows us to analyze the representational properties of a deep Gaussian process by simply examining the properties of products of independent Gaussian matrices, a well-studied object.

1.4 Formalizing a Pathology

? argue that a good latent representation is invariant in directions orthogonal to the manifold on which the data lie. Conversely, a good latent representation must also change in directions tangent to the data manifold, in order to preserve relevant information. Figure 1.3 visualizes this idea. We follow ? in characterizing the representational properties of a function by the singular value spectrum of the Jacobian. In their ex-

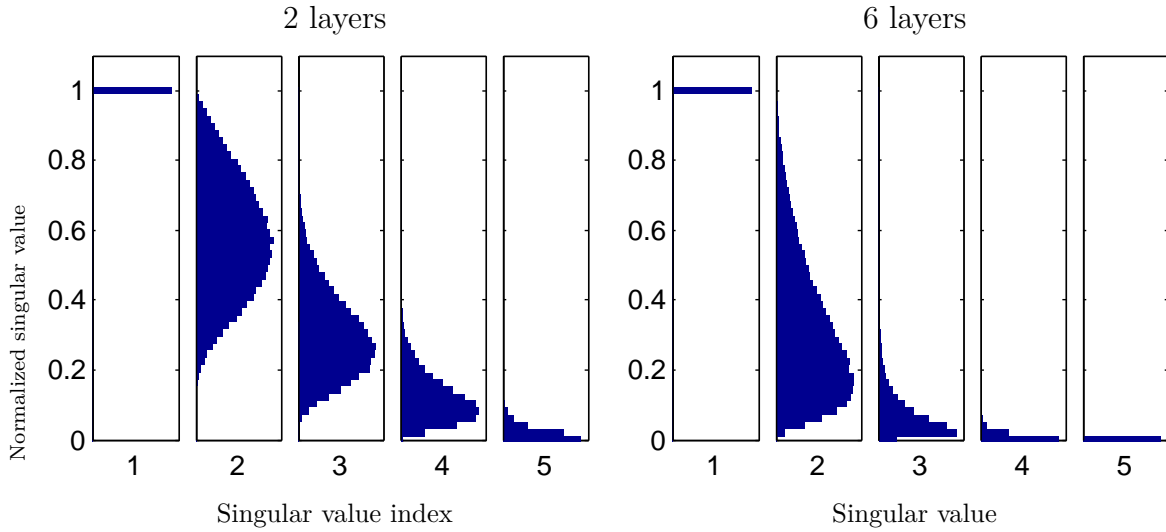

Fig. 1.4 The normalized singular value spectrum of the Jacobian of a deep GP. As the net gets deeper, the largest singular value dominates. This implies that with high probability, there is only one effective degree of freedom in the representation being computed.

periments, the Jacobian was computed at the training points. Because the priors we are examining are stationary, the distribution of the Jacobian is identical everywhere.

Figure 1.4 shows the singular value spectrum for 5-dimensional deep GPs of different depths. As the net gets deeper, the largest singular value dominates, implying there is usually only one effective degree of freedom in representation being computed.

Figure 1.5 demonstrates a related pathology that arises when composing functions to produce a deep density model. The density in the observed space eventually becomes locally concentrated onto one-dimensional manifolds, or *filaments*, implying that such models are unsuitable to model manifolds whose underlying dimensionality is greater than one.

To visualize this pathology in another way, figure 1.6 illustrates a colour-coding of the representation computed by a deep GP, evaluated at each point in the input space. After 10 layers, we can see that locally, there is usually only one direction that one can move in \mathbf{x} -space in order to change the value of the computed representation. This means that such representations are likely to be unsuitable for decision tasks that depend on more than one property of the input.

To what extent are these pathologies present in nets being used today? In simulations, we found that for deep functions with a fixed latent dimension D , the singular value spectrum remained relatively flat for hundreds of layers as long as $D > 100$. Thus,

Fig. 1.5 Visualization of draws from a deep GP. A 2-dimensional Gaussian distribution (top left) is warped by successive functions drawn from a GP prior. As the number of layers increases, the density concentrates along one-dimensional filaments.

these pathologies are unlikely to severely affect relatively shallow, wide networks.

Fig. 1.6 Feature mapping of a deep GP. Colors correspond to the location $\mathbf{y} = \mathbf{f}(\mathbf{x})$ that each point is mapped to after being warped by a deep GP. The number of directions in which the color changes rapidly corresponds to the number of large singular values in the Jacobian. Just as the densities in figure 1.5 became locally one-dimensional, there is usually only one direction that one can move \mathbf{x} in locally to change \mathbf{y} . This means that \mathbf{f} is unlikely to be a suitable representation for decision tasks that depend on more than one aspect of \mathbf{x} .

Fig. 1.7 Two different architectures for deep neural networks. The standard architecture connects each layer's outputs to the next layer's inputs. The input-connected architecture also connects the original input \mathbf{x} to each layer.

Fig. 1.8 Draws from a 1D deep GP prior with each layer connected to the input. Even after many layers, the functions remain smooth in some regions, while varying rapidly in other regions. Compare to standard-connectivity deep GP draws shown in figure 1.2.

1.5 Fixing the Pathology

Following a suggestion from ?, we can fix the pathologies exhibited in figures 1.5 and 1.6 by simply making each layer depend not only on the output of the previous layer, but also on the original input \mathbf{x} . We refer to these models as *input-connected* networks. Figure 1.7 shows a graphical representation of the two connectivity architectures. Similar connections between non-adjacent layers can also be found in the primate visual cortex (?). Formally, this functional dependence can be written as

$$\mathbf{f}^{(1:L)}(\mathbf{x}) = \mathbf{f}^{(L)}\left(\mathbf{f}^{(1:L-1)}(\mathbf{x}), \mathbf{x}\right), \quad \forall L \quad (1.16)$$

Draws from the resulting prior are shown in figures 1.8, 1.9 and 1.11. The Jacobian of the composed, input-connected deep function is defined by the recurrence

$$J^{1:L}(\mathbf{x}) = J^L \begin{bmatrix} J^{1:L-1} \\ I_D \end{bmatrix}. \quad (1.17)$$

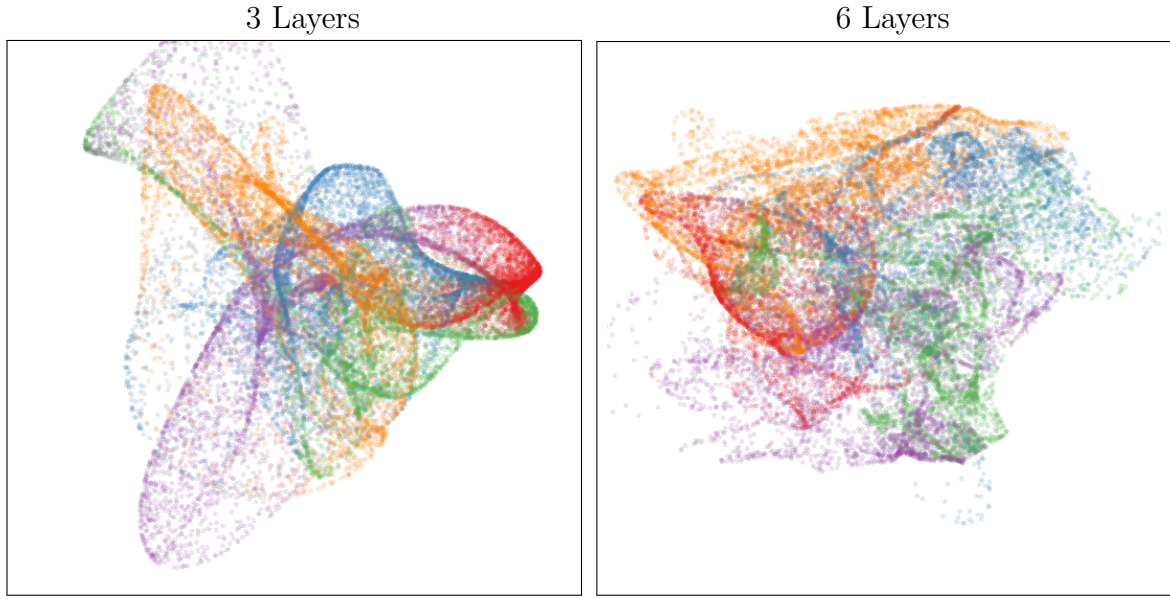

Fig. 1.9 Left: Densities defined by a draw from a deep GP, with each layer connected to the input \mathbf{x} . As depth increases, the density becomes more complex without concentrating along filaments.

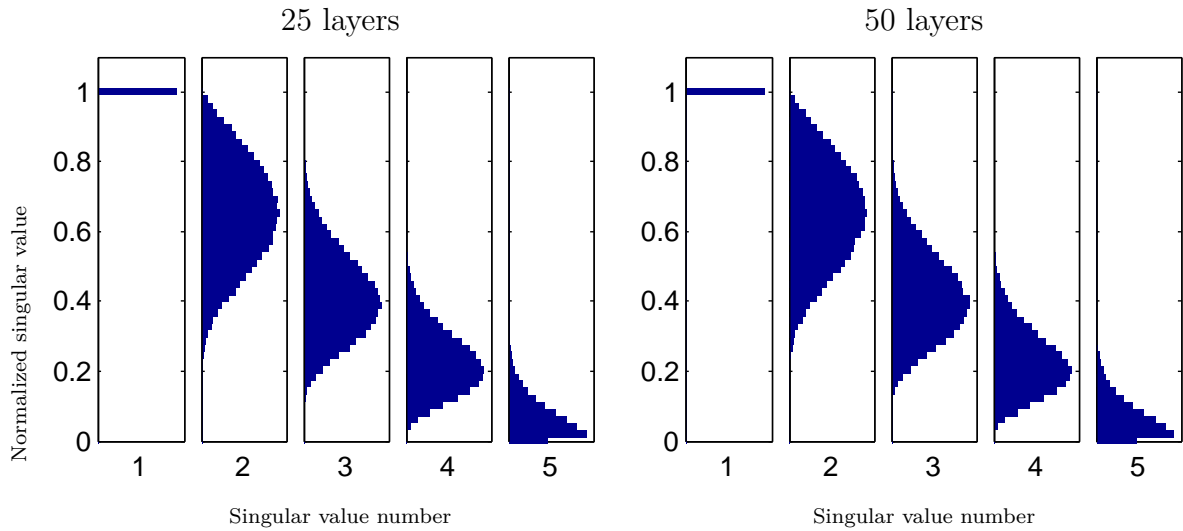

Fig. 1.10 The distribution of singular values drawn from 5-dimensional input-connected deep GP priors 25 and 50 layers deep. The singular values remain roughly the same scale as one another.

Figure 1.10 shows that with this architecture, even 50-layer deep GPs have well-behaved singular value spectra.

Fig. 1.11 Feature mapping of a deep GP with each layer connected to the input \mathbf{x} . Just as the densities in figure 1.9 remained locally two-dimensional even after many transformations, in this mapping there are often two directions that one can move locally in \mathbf{x} in order to change the values of $\mathbf{f}(\mathbf{x})$. This means that the prior puts mass on representations which sometimes depend on all aspects of the input. Compare to figure 1.6.

1.6 Deep Kernels

? showed that kernel machines have limited generalization ability when they use a local kernel such as the squared-exp. However, many interesting non-local kernels can be constructed which allow non-trivial extrapolation. For example, periodic kernels can be viewed as a 2-layer-deep kernel, in which the first layer maps $x \rightarrow [\sin(x), \cos(x)]$, and the second layer maps through basis functions corresponding to the SE kernel.

Can we construct other useful kernels by composing fixed feature maps several times, creating deep kernels? ? constructed kernels of this form, repeatedly applying multiple layers of feature mappings. We can compose the feature mapping of two kernels:

$$k_1(\mathbf{x}, \mathbf{x}') = \mathbf{h}_1(\mathbf{x})^\top \mathbf{h}_1(\mathbf{x}') \quad (1.18)$$

$$k_2(\mathbf{x}, \mathbf{x}') = \mathbf{h}_2(\mathbf{x})^\top \mathbf{h}_2(\mathbf{x}') \quad (1.19)$$

$$(k_1 \circ k_2)(\mathbf{x}, \mathbf{x}') = k_2(\mathbf{h}_1(\mathbf{x}), \mathbf{h}_1(\mathbf{x}')) \quad (1.20)$$

$$= [\mathbf{h}_2(\mathbf{h}_1(\mathbf{x}))]^\top \mathbf{h}_2(\mathbf{h}_1(\mathbf{x}')) \quad (1.21)$$

Composing the squared-exp kernel with any implicit mapping $\mathbf{h}(\mathbf{x})$ has a simple closed form:

$$\begin{aligned} k_{L+1}(\mathbf{x}, \mathbf{x}') &= k_{SE}(\mathbf{h}(\mathbf{x}), \mathbf{h}(\mathbf{x}')) = \\ &= \exp\left(-\frac{1}{2}\|\mathbf{h}(\mathbf{x}) - \mathbf{h}(\mathbf{x}')\|_2^2\right) \\ &= \exp\left(-\frac{1}{2}\left[\mathbf{h}(\mathbf{x})^\top \mathbf{h}(\mathbf{x}) - 2\mathbf{h}(\mathbf{x})^\top \mathbf{h}(\mathbf{x}') + \mathbf{h}(\mathbf{x}')^\top \mathbf{h}(\mathbf{x}')\right]\right) \\ &= \exp\left(-\frac{1}{2}\left[k_L(\mathbf{x}, \mathbf{x}) - 2k_L(\mathbf{x}, \mathbf{x}') + k_L(\mathbf{x}', \mathbf{x}')\right]\right) \end{aligned} \quad (1.22)$$

Thus, we can express k_{L+1} exactly in terms of k_L .

1.6.1 Infinitely Deep Kernels

What happens when we repeat this composition of feature maps many times, starting with the squared-exp kernel? In the infinite limit, this recursion converges to $k(\mathbf{x}, \mathbf{x}') = 1$ for all pairs of inputs, which corresponds to a prior on constant functions $f(\mathbf{x}) = c$.

A non-degenerate construction As before, we can overcome this degeneracy by connecting the inputs \mathbf{x} to each layer. To do so, we simply augment the feature vector

Fig. 1.12 Left: Input-connected deep kernels. By connecting the inputs \mathbf{x} to each layer, the kernel can still depend on its input even after arbitrarily many layers of computation. Right: GP draws using deep input-connected kernels.

$\mathbf{h}_L(\mathbf{x})$ with \mathbf{x} at each layer:

$$\begin{aligned}
 k_{L+1}(\mathbf{x}, \mathbf{x}') &= \exp \left(-\frac{1}{2} \left\| \begin{bmatrix} \mathbf{h}_L(\mathbf{x}) \\ \mathbf{x} \end{bmatrix} - \begin{bmatrix} \mathbf{h}_L(\mathbf{x}') \\ \mathbf{x}' \end{bmatrix} \right\|_2^2 \right) \\
 &= \exp \left(-\frac{1}{2} [k_L(\mathbf{x}, \mathbf{x}) - 2k_L(\mathbf{x}, \mathbf{x}') + k_L(\mathbf{x}', \mathbf{x}') - \|\mathbf{x} - \mathbf{x}'\|_2^2] \right) \quad (1.23)
 \end{aligned}$$

For the SE kernel, this repeated mapping satisfies

$$k_\infty(\mathbf{x}, \mathbf{x}') - \log(k_\infty(\mathbf{x}, \mathbf{x}')) = 1 + \frac{1}{2} \|\mathbf{x} - \mathbf{x}'\|_2^2 \quad (1.24)$$

The solution to this recurrence has no closed form, but has a similar shape to the Ornstein-Uhlenbeck covariance $k_{\text{OU}}(x, x') = \exp(-|x - x'|)$ with lighter tails. Samples from a GP prior with this kernel are not differentiable, and are locally fractal.

1.6.2 When are Deep Kernels Useful Models?

Kernels correspond to fixed feature maps, and so kernel learning is an example of implicit representation learning. Such feature maps can capture rich structure (?), and can enable many types of generalization, such as translation and rotation invariance in images (?). ? used a deep neural network to learn feature transforms for kernels, which learn invariances in an unsupervised manner. The relatively uninteresting properties of the kernels derived in this section simply reflect the fact that an arbitrary deep computation is not usually a useful representation, unless combined with learning.

1.7 Related Work

Deep GPs were first proposed by ?. Variational inference in deep GPs was developed by ?, who also analyzed the effect of automatic relevance determination in that model.

? proposed a prior on deep Bayesian networks. Their architecture has no connections except between adjacent layers, and may also be expected to have similar pathologies as deep GPs as the number of layers increases. Deep Density Networks (?) were constructed with invertibility in mind, with penalty terms encouraging the preservation of information about lower layers. Such priors are a promising approach to alleviating the pathology discussed in this paper.

Recurrent networks ? and ? analyze a related problem with gradient-based learning in recurrent nets, the “exploding-gradients” problem. ? analyze deep kernels corresponding to recurrent neural networks.

Analysis of deep learning ? perform a layer-wise analysis of deep networks, and note that the performance of MLPs degrades as the number of layers with random weights increases. The importance of network architectures relative to learning has been examined by ?. ? looked at the dynamics of learning in deep linear models, as a tractable approximation to deep neural networks.

1.8 Conclusions

In this work, we attempted to gain insight into the properties of deep neural networks by characterizing the sorts of functions likely to be obtained under different choices of priors on compositions of functions.

First, we identified deep Gaussian processes as an easy-to-analyze model corresponding to multi-layer preceptrons with nonparametric activation functions. We then showed that representations based on repeated composition of independent functions exhibit a pathology where the representations becomes invariant to all directions of variation but one. Finally, we showed that this problem could be alleviated by connecting the input to each layer.

We also examined properties of deep kernels, corresponding to arbitrarily many compositions of fixed features. Finally, we derived models obtained by performing dropout on Gaussian processes, finding a tractable approximation to exact dropout in GPs.
